

LinkedIn post — anatomy_skeleton (THE SKELETON)

Most software architecture diagrams show services.

Ours shows bones.

Twelve service repositories. Each one is a named structural element. Some are axial — remove them and the organism collapses. Others are appendicular — removable without killing the system, but posture degrades.

The axial spine: four load-bearing repos.

szl-doctrine holds the 9-axis conjunctive gate, the HUKLLA tripwire table, and the YAWAR write doctrine. It is the vertebral column. The other three axial repos — szl-yawar (the append-only receipt bus), szl-hatun (the sovereign RAID loop orchestrator), and szl-terra (the React 18 BodyGraph surface) — are the vertebrae that make posture possible.

The appendicular bones: eight capability repos.

szl-brain, szl-overwatch, szl-wires, szl-rimay, szl-sentra, szl-tupu-t7, szl-chakana, szl-brand. Each is a limb or rib. The system walks without them. But it walks with a limp, and the limp is visible in the receipt chain.

Why twelve, not forty.

Scope is a structural property. A skeleton with too many bones is a liability: more joints, more failure surfaces, more coordination overhead. Twelve repos means twelve audit targets, twelve deployment surfaces, twelve places where a commit can alter system behavior. That number is deliberate. We track it.

The skeletal frame is a constraint, not a catalog.

An architecture diagram lists what exists. The skeleton tells you what the system requires to stand. The distinction matters when you are debugging at 2 AM and need to know which repo contains the load path.

What the diagram shows.

Axial repos carry a gold border. Appendicular repos in two columns: left (brain, overwatch, wires, rimay) and right (sentra, tupu-t7, chakana, brand). Each card shows language, estimated SLOC, and operational status. Connectors between cards and the central spine represent dependency, not data flow.

Data flow is the nervous system. That is a different diagram.
